Abstract

Here we take a first step towards tackling the challenge of incomplete optical absorption in monolayers of transition metal dichalcogenides for conversion of photon energy, including solar, into other forms of energy. We present a monolayer MoS₂-based photoelectrode architecture that exploits nanophotonic light management strategies to enhance absorption within the monolayer of MoS₂, while simultaneously integrating an efficient charge carrier separation mechanism facilitated by a MoS₂/NiO_x heterojunction. Specifically, we demonstrate two extremely thin photoelectrode architectures for solar-fuel generation: (i) A planar optical cavity architecture MoS₂/NiO_x/Al that improves optical impedance matching and (ii) an architecture employing plasmonic silver nanoparticles (Ag NPs) MoS₂/Ag NPs/NiO_x/Al that further improves light absorption within the monolayer. We used a combination of numerical simulations, analytical models and experimental optical characterizations to gain insights in the contributions of optical impedance matching versus plasmonic near-field enhancement effects in our plasmonic photoelectrode structures. By performing three-dimensional electromagnetic simulations, we predict structures that can absorb 37 % of the incident light integrated from 400 to 700 nm within a monolayer of MoS₂, a 5.9x enhanced absorption compared to that of MoS₂ on a sapphire (Al₂O₃) substrate. Experimentally, a 3.9x absorption enhancement is observed *in the total structure* compared to that of MoS₂/Al₂O₃, and photoluminescence measurements suggest this enhancement largely arises from absorption enhancements within the MoS₂ layer alone. The results of these measurements also confirm that our MoS₂/NiO_x/Al structures do indeed facilitate efficient charge separation, as required for a photoelectrode. To rapidly explore the parameter space of plasmonic photoelectrode architectures we also developed an analytical model based on an effective medium model that is in excellent agreement with results from numerical FDTD simulations.

KEYWORDS: Monolayer molybdenum disulfide (MoS₂), two-dimensional (2D) materials, plasmonics, absorption engineering, photoelectrode architecture, photocatalysis.

Monolayer MoS₂ is a promising material for several classes of optoelectronic devices¹⁻⁹ and photocatalytic applications¹⁰⁻¹². In contrast to multilayer MoS₂, monolayer MoS₂ has a direct band gap around 1.8 eV (690 nm). This band gap is ideal for a photoelectrode for solar water splitting based on a single semiconductor¹¹ and enables broadband light absorption in the visible and ultraviolet regions. Furthermore, the bandgap of monolayer MoS₂ is ideal for tandem cells which achieve highest power conversion efficiencies if two materials with band gaps of 1.1 eV and 1.8 eV are combined^{5,11,13-15}. The electronic structure and the conduction and valence band edge positions of monolayer MoS₂, in contrast to multilayer MoS₂, are also near-ideal for driving the water splitting reactions^{11,16,17}. Furthermore, MoS₂ is currently extensively explored as a nonprecious hydrogen evolution reaction catalyst^{10,11,18-21} with a performance potentially rivaling that of expensive platinum. Notwithstanding the unique properties that monolayer transition metal dichalcogenides (TMDC) such as molybdenum disulfide (MoS₂) have to offer, the low light absorption in monolayers limits their use in photocatalytic applications and energy-efficient optoelectronic devices^{22,23}. Therefore, intensive research efforts worldwide are directed at achieving efficient and application-tailored light absorption within two-dimensional monolayer architectures²⁴⁻²⁷.

Monolayer MoS₂ absorbs less than 8%¹³ of the incident light in the 400 to 700 nm range when supported on a planar silica substrate. A recent numerical study predicted the possibility of broadband absorption of up to 33 % in monolayer MoS₂ that was sandwiched within a sophisticated chirped distributed Bragg cavity design, intended for a photodetector application²⁴. Another approach to enhance light absorption within nanoscale regions is the utilization of plasmonic nanoantennas^{28,29,30}. A first demonstration of plasmon-enhanced light absorption within monolayer MoS₂ was reported by Britnell et al.³¹ who spattered gold nanoparticles on top of MoS₂

and observed a 10-fold increase in the photocurrent at 633 nm. Sobhani et al.³² employed silica-core gold-shell nanoparticles with a surface coverage of less than 1% and demonstrated a 3-fold increase in the photocurrent and a 2-fold increase in the photoluminescence at the excitonic transitions of 630 nm and 680 nm of MoS₂ near the band-edge. While plasmonic gold nanostructures can enhance light absorption and photoluminescence near the band gap of MoS₂, they are not suitable for broadband absorption enhancements required for solar energy conversion devices, since the interband transitions in gold tend to suppress light absorption at short wavelengths.

In this article, we explore novel photoelectrode architectures based on single-layer molybdenum disulfide (MoS₂) that employ broadband absorption engineering strategies from 400 to 700 nm, while simultaneously incorporating an efficient charge carrier separation mechanism. First, we investigated a planar optical cavity MoS₂/NiO_x/Al that improves optical impedance matching. Optical impedance matching is achieved when reflection from the architecture can be completely suppressed, i.e. the amplitude and phase of the first reflection coefficient are perfectly canceled by all the other reflections. Secondly, to increase light absorption within the monolayer even further, we designed an architecture employing plasmonic silver nanoparticles, MoS₂/Ag NPs/NiO_x/Al. The plasmonic structure can absorb up to 37 % of the incident light within the monolayer of MoS₂ integrated from 400 to 700 nm based on finite difference time domain (FDTD) simulations. Photoluminescence measurements from MoS₂ are correlated with absorption measurements, and show that absorption indeed occurs *within* the monolayer *rather than elsewhere* in the photoelectrode architecture. These measurements also confirm that MoS₂/NiO_x/Al structures facilitate efficient charge separation, as required for a photoelectrode. Since three-dimensional electromagnetic simulations can be time-consuming, we explored whether analytical models can

be used to predict the tuning parameters for enhanced light absorption. We found that absorption within our full plasmonic photoelectrode architecture can be described in very good agreement with full-field electromagnetic simulations.

Results and Discussion

Figure 1a shows the measured and simulated absorbed fraction as a function of wavelength for $\text{MoS}_2/40\text{ nm NiO}_x/\text{Al}$ where a 40 nm NiO_x spacer thickness provides the best optical impedance matching as predicted by three-dimensional FDTD simulations. As a control, we also fabricated $\text{MoS}_2/45\text{ nm Al}_2\text{O}_3/\text{Al}$ (Figure 1b), an optimally impedance-matched structure that does not support charge carrier separation since Al_2O_3 is an insulator, but forms a near-identical photonic cavity since the dielectric constants of Al_2O_3 are very close to those of NiO_x . Absorption enhancements were referenced to planar MoS_2 on SiO_2 (Al_2O_3) substrates, respectively. Figures 1a and 1b show the experimental and simulated absorption spectra in these structures. From simulations we find that approximately 74% of the incident light is absorbed within MoS_2 (88% in total structure) at 425 nm (Supporting Information S1), corresponding to a six times stronger absorption at 425 nm compared to that of MoS_2 on a glass (SiO_2) substrate. Experimentally, the absorbed fraction rises to 69% at 450 nm for $\text{MoS}_2/\text{NiO}_x/\text{Al}$ compared to 12% for MoS_2 on SiO_2 (Figure 1). The good agreement between simulations and experimental results in these planar MoS_2 architectures shows that better optically impedance matched architectures can strongly enhance light absorption in monolayer MoS_2 - a first step towards energy-efficient optoelectronic and photocatalytic devices that would benefit from the unique electronic and catalytic properties of monolayer MoS_2 .

To get a more direct experimental assessment of the increased absorbed fraction *within the monolayer MoS₂ alone*, we carried out a set of absorption and photoluminescence measurements in the same sample. We note that these were performed on a slightly less optimally impedance matched structure in which the dielectric spacer layer was too thin (40 nm Al₂O₃) to achieve optimum absorption in the monolayer, but the conclusions are robust against small variations in device parameters.

To get a more direct experimental assessment of the increased absorbed fraction *within the monolayer MoS₂ alone* we performed localized photoluminescence (PL) measurements of MoS₂ on three substrates: (i) Al₂O₃ (sapphire), (ii) 40 nm Al₂O₃/Al, and (iii) 40 nm NiO_x/Al. Figure 2 shows the variation of the PL signal strength of monolayer MoS₂ acquired on sample (i), a triangular flake of single-layer MoS₂ on Al₂O₃ and at approximately the same location after transferring the MoS₂ to 40 nm Al₂O₃/Al (sample (ii)). We also show the PL signal obtained from sample (iii), MoS₂ on 40 nm NiO_x/Al exfoliated from a SiO₂ growth substrate. The presence of the strong A / A'- exciton peak around 670 nm is a clear indication of the direct gap transition at the K point of the Brillouin zone in monolayer MoS₂ and becomes much weaker for multilayer MoS₂³³⁻³⁵. For the MoS₂/40 nm Al₂O₃/Al architecture, we find that the PL signal strength increases 3.2 x compared to MoS₂/Al₂O₃ (Figure 2). The close correspondence of this PL enhancement, arising from MoS₂ alone, to the above-mentioned measured 3.9 x absorption enhancement in the total structure (Supporting Information S2) demonstrates that the improved light absorption occurred largely *within the monolayer* of MoS₂. We note that no strong additional enhancement due to emission outcoupling³⁶ is anticipated because the electric field has no antinode in the MoS₂ at the photoluminescence wavelength of 670 nm (Figure 5a). This attribution is furthermore supported by numerical simulations that predict an increase of absorption *within the monolayer* from 6.3%

1
2
3 for MoS₂/Al₂O₃ to 25.1% for MoS₂/40 nm Al₂O₃/Al (i.e. an enhancement of 4x) (Supporting
4 Information S3). A similar improvement in light absorption *within the monolayer* of MoS₂ is
5
6 expected for MoS₂/40 nm NiO_x/Al since the dielectric constants of NiO_x are close to those of
7
8 Al₂O₃.
9
10

11
12
13
14 When instead PL is measured from MoS₂ on the NiO_x spacer/Al layer, the PL strength of
15
16 monolayer MoS₂ is reduced by 2.5x (Figure 2) or even more (Supporting Information S4)
17
18 compared to that of MoS₂/Al₂O₃ (sapphire substrate), which is surprising given the apparent
19
20 integrated enhancement of the absorption of three times in the 400 to 700 nm region. Since the
21
22 photonic cavity is the same (the refractive index for both wide band gap dielectric spacer layers
23
24 NiO_x and Al₂O₃ is approximately $n = 1.8$) we can exclude any optics-based explanation for the
25
26 reduced photoluminescence, and instead attribute the reduction of the PL strength to hole
27
28 scavenging by the underlying NiO_x substrate. The Raman signal strengths from MoS₂ support the
29
30 conclusions drawn from these PL measurements (Supporting Information S5): We observed a 17x
31
32 enhancement in the Raman signal (area under the peaks at 387 cm⁻¹ and 405 cm⁻¹) for monolayer
33
34 MoS₂ on top of Al₂O₃/Al compared to an Al₂O₃ substrate when excited by a 514.5 nm laser. We
35
36 attribute the strong Raman signal to the increased absorption in MoS₂ and an improved outcoupling
37
38 from our structure at 514 nm³⁶ (Figure 5). The Raman signal was about 4x stronger for
39
40 MoS₂/NiO_x/Al than that for MoS₂/ SiO₂ (Supporting Information S5), and we assume here that
41
42 hole transfer from MoS₂ to p-type NiO_x upon photoexcitation of MoS₂ populates the electronic
43
44 ground state and reduces outcoupling.
45

51
52
53 To explain this hole scavenging effect, we draw an energy band schematic for the MoS₂/NiO_x
54
55 and MoS₂/Al₂O₃ interface (Figure 3). The Fermi levels of a single layer of MoS₂ and NiO_x were
56
57 previously reported at 4.7 eV³⁷⁻³⁹ and 5.0 eV⁴⁰⁻⁴² resulting in a 0.3 eV energy level offset (Figure
58
59
60

3a), which causes an electrostatic field at the heterojunction interface that can facilitate charge carrier separation, and represents a promising alternative to recently investigated type II two-dimensional (2D) heterojunctions⁴³⁻⁴⁵. Upon illumination, the photogenerated holes of MoS₂ drift to the energetically more favorable valence band of NiO_x, leaving the electron behind; this spatial separation of charge carriers leads to the observed PL quenching in the MoS₂/NiO_x/Al structure (Figure 2). We performed Mott-Schottky (M-S) measurements⁴⁶⁻⁵⁰ in a three-electrode electrochemical cell setup to verify the p-type properties^{40,42,50,51} of our 40 nm thick NiO_x thin films on an Al back electrode. When instead Al₂O₃⁵² is used as a spacer layer, an enhancement of photoluminescence strength is observed, consistent with our expectations, since none of the photogenerated carriers in MoS₂ can be transferred to Al₂O₃ (Figure 3b). We anticipate that the enhanced absorption within monolayer MoS₂ and charge separation at the MoS₂/NiO_x interface can be exploited for improved optoelectronic, photovoltaic and photocatalytic devices that require the unique properties of single-layer MoS₂. It should be noted that placing MoS₂ directly on an Al reflector⁵³ instead of using an optical cavity with a dielectric spacer layer MoS₂/NiO_x/Al results in a significantly reduced absorption within MoS₂ even lower than on a sapphire substrate (Supporting Information S6).

To increase the absorption further, and over a broad range extending from 400 to 700 nm relevant for solar energy conversion devices, as opposed to narrowband spectral regions near the band gap⁵⁴, we also fabricated and investigated *plasmonic photoelectrode architectures* MoS₂/Ag NPs/NiO_x/Al. Our three-dimensional full-field electromagnetic simulations predict that plasmonically active Ag nanoparticles can further improve absorption *within the monolayer* of MoS₂ to a final value of 37% for Ag NPs/45nm Al₂O₃/Al (Figure 4a,b, and Supporting Information Figure S7) and 35% for Ag NPs/40nm NiO_x/Al in the wavelength region from 400 to 700 nm. We

find that adding silver nanoparticles *below* MoS₂ can offer the largest enhancements in light absorption as compared to Ag nanoparticles *on top* of MoS₂ or without plasmonic Ag particles (Supporting Information S7).

Hence, in all our experimental plasmonic structures, plasmonic Ag nanoparticles were incorporated underneath the monolayer MoS₂ (Figures 1 and 4). We achieved the largest broadband absorption enhancement when the plasmon resonance of the Ag NPs is located close to 670 nm, near the band gap of MoS₂. To predict the desired thickness of plasmonic Ag nanoislands embedded in air, we performed 3D FDTD simulations, and found that a thickness of 5 to 15 nm is optimum for maximum energy transfer to MoS₂ (Supporting Information S8). The FDTD simulations were performed on structures with Ag nanodisks.

Experimentally we found that e-beam deposition of a thicker silver layer formed a thin film rather than Ag nanoislands. Hence, we deposited 5 and 7 nm thick Ag nanoparticles by e-beam evaporation, which resulted in particle diameters of around 30 nm and 100 nm, respectively. We calculated the total absorbed fraction (Figure 1) and the absorbed fraction within different layers and within the Ag nanoparticles (Figure 4) of the structure from the E-field distributions predicted by FDTD simulations^{28,55} (Supporting Information S9). Figure 4a shows the simulated absorbed fraction within monolayer MoS₂ for the MoS₂/Al₂O₃/Al architecture with and without the Ag nanodisks (30 nm diameter, 5 nm thick) placed on top of the spacer layer, and for monolayer MoS₂ on top of Al₂O₃ for comparison. The results with a NiO_x spacer layer are essentially the same due to the nearly identical refractive index. In Figure 4b, the simulated absorbed fraction integrated from 400 to 700 nm in each layer of the total structure is shown for the photoelectrode architecture with and without Ag nanoparticles. As can be seen from the bar chart the integrated absorbed fraction within monolayer MoS₂ increases from 32 % (a 5x enhanced absorption compared to that

of MoS₂/Al₂O₃) to 37 % (a 5.9x enhanced absorption compared to that of MoS₂/Al₂O₃) by the incorporation of Ag nanoparticles while the absorbed fraction by the spacer and reflector layers and also the reflected fraction of the incident light decrease. Less than 11% of the incident photons are lost due to absorption in the Ag NPs (Supporting Information S18, S19). These results further support our claim of enhanced light absorption within monolayer MoS₂ and support the high experimentally measured absorbed fraction of larger than 80 % around 450 nm for MoS₂/Ag NPs/Al₂O₃/Al and MoS₂/Ag NPs/NiO_x/Al, with the majority of light being absorbed in the monolayer (Figure 1). The measured absorption in the total plasmonic photoelectrode structure is larger than that predicted by the simulations in the wavelength region above 450 nm, likely due to imperfections and nonuniform coalescence of CVD-grown MoS₂ triangles into a monolayer, as a result exposing some of the Ag NPs: In regions not covered with the MoS₂ top layer the Ag NPs are strongly absorbing (Supporting Information 18). Furthermore, the experimentally measured spectrum is broadband due to the superposition of plasmon oscillations of different sizes, shapes, densities and couplings of Ag particles (see Supporting Information S10). Further experimental imperfections may arise from the thickness uniformity of the spacer layer and the uniformity of its optical properties, and the roughness of the aluminum substrate.

In order to distinguish whether the improved absorption within MoS₂ in our architectures containing Ag NPs is mainly due to optical impedance matching effects or plasmonic near-field enhancement effects we plot the electric field energy profile along the direction of normal incident light in Figure 5a. A strong standing-wave electric field can be observed, indicating significant reflection from both architectures with and without Ag NPs, and showing that there is room left to further improve optical impedance matching of the active layer MoS₂ to the incident medium. Comparing the intensity amplitudes of the near-fields in the presence of Ag NPs to those of the

standing wave pattern at the position of the MoS₂ monolayer, we find that at long wavelengths the absorption enhancement within the MoS₂ monolayer can be attributed mainly to plasmonic near-field concentration effects rather than optical impedance matching (Figure 4, Figure 5) (Note, the plasmon resonance in the absence of MoS₂ is located around 662 nm for an Al₂O₃ and around 683 nm for a NiO_x substrate). Figure 5b shows the modulus squared of the light's electric field, and we see most enhancement in the electric field at wavelengths close to the plasmon resonance, which is also near the band gap of MoS₂. A slight suppression is instead observed at 430 nm.

Three-dimensional electromagnetic simulations can be time consuming. For this reason we also explored how well simple analytical models can predict the parameters for enhanced light absorption within our plasmonic photoelectrode structures. To gain an intuition for the optical effects of these metal nanoparticles, one may think of the layer of particles and their host medium as an effective medium. Plasmonic metals possess a real part of the refractive index η that is much smaller than their imaginary part κ whereas for semiconductors and dielectrics $\eta \gg \kappa$. Therefore, a composite fabricated from suitable components can be tuned to produce an effective medium fulfilling the critical coupling condition^{55,56} leading to perfect light absorption. To maximize the absorption rate in monolayer MoS₂ we combine it with plasmonic silver nanoparticles that are known to provide the lowest optical damping in the visible region⁵⁶, resulting in large E-field enhancements. Furthermore, a wide range of low-cost techniques for fabricating silver nanostructures have been developed including electron beam evaporation⁵⁷, colloidal self-assembly⁵⁸, nanosphere lithography⁵⁹ and block copolymer lithography⁶⁰. Among these techniques, ultrathin films (5-10 nm) of silver evaporated by e-beam physical vapor deposition present a simple one-step and reproducible way to produce nano-islands that exhibit strong local electric field enhancements.

We tested effective medium theories for our plasmonic metamaterial consisting of three components, monolayer MoS₂, and Ag nanodisks (30 nm diameter by 5 nm thick) embedded in air to find the most suitable one for matching our three-dimensional electromagnetic simulation results. This configuration closely resembles our experimentally realized structure. First we employed the Bruggeman effective medium approximation in two dimensions⁶¹ to find the effective dielectric constant for a two-component system of Ag nanoparticles and air. In our case, this material behaves semiconductor-like (Supporting Information S11 B). Then we used the generalized effective medium approach to combine this Ag/air composite with the MoS₂ monolayer. We also tested the Maxwell-Garnett mixing rule, but found the Bruggeman model to yield much better agreement with the electromagnetic simulations (Figure 6). The integrated absorption from 400 to 700 nm in the total plasmonic photoelectrode structure is maximized for a Ag NPs fill fraction of 0.36 for both, the Bruggeman analytical model and numerical FDTD results. Since the FDTD simulations contain the precise information on the size and shape of the nanoparticles in contrast to the effective medium approximations (EMA), and therefore take into account the local plasmonic field enhancements there is still a finite discrepancy between FDTD and EMA results for the geometries containing nanoparticles.

In past work^{55,56} an optical analogue of a Salisbury screen, i.e. a structure containing a reflector layer combined with a dielectric spacer layer at the proper distance from an ultrathin absorber layer made from a plasmonic metamaterial, has been employed to achieve near-100% absorption if the active layer fulfills the critical coupling condition:

$$n_{eff} + i\kappa_{eff} \approx \frac{(1+i)(n_i - \overline{n_s})^{\frac{1}{2}}}{\sqrt{2}} \left(\frac{\lambda_0}{2\pi d_{eff}} \right)^{\frac{1}{2}}, \text{ where } \overline{n_s}(\lambda) = in_s \cot\left(\frac{4n_s h \pi}{2\lambda}\right).$$

Here n_i is the refractive index for the incident medium, n_s the refractive index for the underlying spacer layer, d_{eff} the thickness of the thin active material, h is the spacer layer thickness, and λ_0 is the vacuum wavelength. To predict the theoretical maximum absorption in the total structure we calculated the real and imaginary refractive index for an effective medium layer that fulfills the critical coupling condition (red dash-dotted line, Figure 7)^{55,56}. For our chosen 3-component materials system, i.e., monolayer MoS₂, Ag NPs/air, it is only possible to fulfill the critical coupling condition^{55,56} around 450 nm but not over the full range from 400 to 700 nm.

We plotted the mismatch (Supporting Information S13, S14) of the real and imaginary part of the refractive index of the effective medium layer as a function of wavelength and dielectric spacer layer thickness between the Bruggeman analytical model of our 3-component metamaterial and the effective medium model fulfilling the critical coupling condition⁵⁵ (Supporting Information S12). We used the Ag NPs fill fraction of 0.36 predicted by our Bruggeman effective medium analytical model and in our transfer matrix formalism we used the complex refractive index for the aluminum back reflector when sweeping the dielectric spacer layer thickness.

We find that our 3-component metamaterial can match the real part n_{eff} of the critical coupling condition at around 450 nm but the imaginary part κ_{eff} is off (Supporting Information S13, S14). Note that for this mismatch calculation the spacer layer thickness is too thin by approximately the skin depth since the analytical model for the critical coupling condition is based on the assumption of a perfect electric conductor reflector (Supporting Information S12-S14). We conclude that our Bruggeman effective medium model can predict the optimum Ag fill fraction and dielectric spacer layer thickness in very good agreement with the numerical simulations, and it predicts that the mismatch of the real part n_{eff} w.r.t. the critical coupling condition is zero around 450 nm but the

imaginary part κ_{eff} is off at all wavelengths. It predicts a similar total absorbed fraction in our plasmonic photoelectrode architecture as the numerical simulations (Figure 7).

The detailed analyses and tools developed here will serve as a platform for the design of next-generation photonic, optoelectronic and photocatalytic devices created from 2D materials. Specifically, we demonstrated a simple plasmonic architecture $\text{MoS}_2/\text{AgNPs}/\text{NiO}_x/\text{Al}$ suitable as a photoelectrode to drive photochemical reactions that is numerically predicted to achieve broadband light absorption of 35% within a single layer of MoS_2 , while simultaneously facilitating charge separation. This absorption is on par with results of a recent numerical study that demonstrated broadband absorption up to 33 % in a more complicated chirped-planar-dielectric cavity architecture²⁴ for photodetector applications. Our approach can be easily extended to achieve improved absorption in other photoelectrodes based on two-dimensional metal dichalcogenides. With these results, we have taken a first step towards designing a photoelectrode architecture that utilizes the unique electronic and catalytic^{11,16} properties of monolayer MoS_2 – a known nonprecious and efficient hydrogen evolution catalyst¹¹, while employing photon management strategies to turn monolayer MoS_2 into a more efficient light absorber. For semiconducting MoS_2 , it is commonly assumed that the hydrogen evolution reaction in solar water splitting occurs at the edge sites. Therefore, monolayer-based MoS_2 photoelectrodes may benefit from the introduction of discontinuities, gaps or lateral nanostructures to expose the edge sites efficiently. The effects of the inclusion of Ag nanoparticles, including size- and shape-dependent effects, on the optical, electronic and catalytic properties are beyond the scope of this work. As is commonly done in the current literature, we made the assumption that the dielectric constant of MoS_2 is isotropic in this highly anisotropic material. However, the expected *anisotropy* of the optical properties of monolayer MoS_2 warrants further studies. The models and tools developed

here may serve as a starting point for future studies of optical metamaterials⁶² created from 2D materials.

Methods

We fabricated our structures by first depositing a 200 nm thick aluminum film via electron beam evaporation on a p-type silicon substrate. Next, we deposited either a ~ 40 nm thick NiO_x film by spin-coating, or 40 nm and 45 nm thick Al₂O₃ films by e-beam evaporation as the wide band gap dielectric spacer layer. We prepared NiO_x via a two-step sol-gel method that we adapted following a previously reported recipe^{50,63}. We measured the complex refractive index of both dielectric spacer layers (Supporting Information S15). For our second architecture employing plasmonic silver nanoparticles MoS₂/Ag NPs/NiO_x/Al, we deposited 5 nm thick Ag nanoislands as determined by a quartz crystal oscillator thickness monitor. SEM images (Supporting Information S10) show elongated Ag hemispheres, with diameters varying from 10 to 50 nm and an average inter-particle distance of less than 5 nm at a surface concentration of < 50%. The transfer process of MoS₂ onto the Ag NP/Spacer/Al substrate is described in the Supporting Information S23.

Monolayer MoS₂ films were grown by chemical vapor deposition (CVD) by exposing MoO₃ powder to sulfur vapor at 700 °C temperature using argon as a carrier gas⁶⁴⁻⁶⁶. We synthesized millimeter scale monolayer MoS₂ (Supporting Information S16). To verify regions of monolayer growth we utilized Raman spectroscopy and ensured the two Raman active modes in a MoS₂ exhibit the characteristic wavenumber difference of fewer than 21 cm⁻¹ between the in-plane and the out-of-plane modes⁶⁷. We also determined a thickness of 0.8 nm by atomic force microscopy (AFM) measurements⁶⁷ further supporting monolayer growth. We determined the complex dielectric function of monolayer MoS₂ by measuring the reflectance and transmittance as a function of wavelength⁶⁸. Photoluminescence and Raman measurements were carried out on a

confocal Raman microscope. To avoid local heating and thermal etching in this experiment ⁶⁹, we followed a careful alignment with a laser power of 1.25 mW ⁷⁰.

Our optical characterization measurements were performed with an integrating sphere that takes into account both specular reflection and diffuse scattering. Hence, our inferred absorption values are accurate even in the presence of rough, scattering samples.

‘Supporting Information Available: Reflection microscope images of MoS₂ on different substrates, thin film SEM characterization of the plasmonic nanoparticles, Raman spectroscopy and photoluminescence of MoS₂ on different substrates, optical characterization of Al₂O₃ and NiO_x, electromagnetic simulations/ absorbed fraction in monolayer MoS₂ and in total photoelectrode with and without plasmonic nanoparticles of varying material, size, size distributions, shape and location with respect to monolayer MoS₂, results and comparisons of simulations and analytical models, discussion of possible mechanisms of photoluminescence quenching. Figure 1. Absorption engineering in planar MoS₂ architectures: Experimental results (solid lines) and electromagnetic simulations (dashed lines) used to predict structural parameters. (a) (i) Blue: MoS₂ / SiO₂ as benchmark. (ii) Green: To achieve better light absorption within monolayer MoS₂ we explore improved optical impedance matching in a geometry consisting of MoS₂ on top of a wide band gap dielectric spacer NiO_x and an Al reflector, i.e. MoS₂/ 40 nm NiO_x/ Al. Furthermore, NiO_x is chosen as a spacer layer because it can serve as a scavenger of the photoholes generated in MoS₂ in addition to providing suitable optical properties for optical impedance matching. (iii) Yellow: Plasmonic silver nanoparticles can further enhance the absorption within monolayer MoS₂ in a MoS₂ monolayer/ Ag nanoparticles /NiO_x dielectric spacer /Al reflector geometry. (b) Same as in Figure 1a, but with an Al₂O₃ dielectric spacer layer, i.e. MoS₂/ 45 nm Al₂O₃/ Al, and substrate as a benchmark, i.e. MoS₂ / Al₂O₃. Note that the absorption spectra calculated by FDTD exhibit slight oscillatory artifacts arising from a polynomial fit to the real and imaginary part of the dielectric constant that causes an overestimation of the absorption around 440 nm.

Figure 2. Photoluminescence spectra, excited at 514.5 nm, for (i) MoS₂ on Al₂O₃ (blue), (ii) MoS₂ on 40 nm Al₂O₃/Al (red), and (iii) our target structure MoS₂ on NiO_x/Al designed for efficient charge carrier separation (green). The photoluminescence intensity for planar monolayer MoS₂ on 40 nm Al₂O₃ with an Al reflector (structure (ii)) is increased three times compared to planar monolayer MoS₂ on Al₂O₃ (structure (i)), which supports enhanced absorption in the better optically impedance matched structure. In contrast, in MoS₂ on NiO_x/Al (structure (iii)) the photoluminescence spectrum shows luminescence quenching compared to (i), which we attribute to hole scavenging by the underlying NiO_x substrate (green). Note that the difference in luminescence between (ii) and (iii) is unlikely to be due to a difference in absorption, since the refractive index for both wide band gap dielectric spacer layers NiO_x and Al₂O₃ is approximately $n = 1.8$, and since simulations predict similar absorption over the full wavelength range.

Figure 3. Energy schematic of our structure (a) Left: The energy band diagram for MoS₂ and NiO_x shows the relative positions of the Fermi levels with respect to the vacuum level before establishing a MoS₂-NiO_x contact. Right: The energy band diagram of MoS₂-NiO_x showing band bending after establishing the contact between NiO_x and MoS₂. MoS₂ on NiO_x/Al does not show significant photoluminescence consistent with the presence of an efficient charge separation mechanism in MoS₂ on NiO_x/Al. (b) Band diagram of MoS₂ on top of Al₂O₃/Aluminum. Because of the large energy barrier of Al₂O₃, photogenerated charge carriers cannot be transferred from MoS₂ to Al₂O₃, consistent with the observed highly efficient photoluminescence from this structure.

Figure 4. Simulated fraction of light absorbed within a monolayer of MoS₂, as a function of wavelength. (i) on Al₂O₃ (blue line), (ii) on 45 nm Al₂O₃/Al (yellow line), and (iii) on Ag nanoparticles/45 nm Al₂O₃/Al (purple line). These simulation results predict absorption enhancements within the 7 Å thick monolayer MoS₂ when placed on substrates (ii) and (iii). (b) Comparison of the absorbed fraction (integrated from 400 nm to 700 nm) by individual components in a structure with Ag nanoparticles (purple) and without Ag nanoparticles (yellow). The fraction of light reflected is shown for comparison. The integrated absorbed fraction within monolayer MoS₂ increases by 16% when Ag nanoparticles are incorporated, whereas the absorbed fraction by the spacer and reflector layer and the reflected fraction of light decrease.

Figure 5. Optical impedance matching vs. plasmonic near-field enhancement effects for improved absorption within MoS_2 . (a) Left: Modulus squared of the light's electric field along its axis of propagation for a structure without ($MoS_2/ Al_2O_3/ Al$) and with Ag nanoparticles ($MoS_2/ AgNPs/ Al_2O_3/ Al$), plotted near the wavelength of peak absorption of MoS_2 at 430 nm (purple line) and near the bandgap of MoS_2 at 670 nm (yellow line). Each component of the structure is shown in a different color: Blue as reflector layer, green as spacer layer, yellow as Ag nanoparticle layer and red as MoS_2 absorber layer. (b) The bar chart shows a comparison of the modulus squared of the electric field within monolayer MoS_2 for the two structures with and without Ag NPs at 430 nm and 670 nm. In our structure, the absorption enhancement in MoS_2 in the presence of Ag nanoparticles originates predominantly from near-field concentration effects brought about by the Ag nanoparticles.

Figure 6. Top left: Absorbed fraction of the incident light in the total plasmonic photoelectrode structure MoS₂/Ag NPs/45 nm Al₂O₃/Al as a function of wavelength and Ag nanoparticle fill fraction determined by a transfer matrix model employing the Maxwell Garnett effective medium approximation. Top Right: Absorbed fraction of the incident light in the total plasmonic photoelectrode structure MoS₂/Ag NPs/45 nm Al₂O₃/Al as a function of wavelength and Ag nanoparticle fill fraction determined by a transfer matrix model employing the Bruggeman effective medium approximation. Bottom Left: Absorbed fraction of the incident light in the total plasmonic photoelectrode structure MoS₂/Ag NPs/45 nm Al₂O₃/Al as a function of wavelength and Ag nanoparticle fill fraction determined by FDTD simulations. Bottom Right: Absorbed

fraction of the incident light only within the monolayer of MoS₂ for the plasmonic photoelectrode structure MoS₂/Ag NPs/45 nm Al₂O₃/Al determined by FDTD simulations.

Figure 7. Comparison of the absorption by the total structure predicted by numerical simulations and the analytical model based on the Bruggeman effective medium approximation. The results are also compared with respect to the theoretical maximum absorption that can be achieved if one can match the refractive indices predicted by equation (1), i.e. the analytical model for the critical coupling condition.
