The First Pulse of the Extremely Bright GRB 130427A: A Test Lab for Synchrotron Shocks

Gamma-ray burst (GRB) 130427A is one of the most energetic GRBs ever observed. The initial pulse up to 2.5 seconds is possibly the brightest well-isolated pulse observed to date. A fine time resolution spectral analysis shows power-law decays of the peak energy from the onset of the pulse, consistent with models of internal synchrotron shock pulses. However, a strongly correlated power-law behavior is observed between the luminosity and the spectral peak energy that is inconsistent with curvature effects arising in the relativistic outflow. It is difficult for any of the existing models to account for all of the observed spectral and temporal behaviors simultaneously.

In the context of Gamma-ray burst (GRB) 130427A, which triggered the Gamma-Ray Burst Monitor (GBM) (J) on the Fermi Gamma-Ray Space Telescope on 27 April 2013 at T₀ = 07:47:06.42 UTC (2–4) is an extreme case. The peak flux on the 64-ms time scale is 1300 ± 100 photons s⁻¹ cm⁻² in the 10 to 1000 keV range and the fluence, integrated over the same energy range and a total duration of ~350 s, is (2.4 ± 0.1) × 10⁻³ erg cm⁻². The longest continuously running GRB detector, Konus on the Wind spacecraft, has been observing the entire sky for nearly 18 years, and only one burst had a larger peak flux by ~30% (GRB 110918A) (5). GRB 130427A is the most fluent burst in the era starting with the 1991 launch of the Burst and Transient Source Experiment (BATSE) on the Compton Gamma-Ray Observatory. Finally, the energy of the spectral peak in the first time bin (T₀ ≈ 0.1 to 0.0 s), 5400 ± 1500 keV, is the second highest ever recorded (6).

The initial pulse (Fig. 1), lasting up to 2.5 s after the trigger, stands on its own as being so bright (170 ± 10 photons s⁻¹ cm⁻² peak flux for 10 to 1000 keV in the 64-ms time bin at T₀ = 0.51 s) as to be ranked among the 10 brightest GRB or BATSE bursts (7–9). The brightness allows us to track the spectral evolution of the rising portion of a well-separated pulse with unprecedented detail (10). Evident in the GRB low-energy light curve (Fig. 1; as well as the 15 to 350 keV light curve presented in (11)] are fluctuations starting at around 1 s that are not present at higher energies. If these represent additional low-energy pulses, their presence clearly does not dominate the analyses presented below.

Past studies of time-resolved spectra of simple pulses in GRBs indicate that there are broadly two classes of spectral evolution. These are called “hard-to-soft” and “soft-to-hard” pulses (12, 13), depending on whether the energy of the peak in the νFν spectrum (generically called Epeak herein) monotonically decays independently of the flux evolution or else generally follows the rise and fall of the flux. Typically, there are at most one or two spectra available for fitting during the rising portion of the flux history. What makes this event unique is that there are roughly six time bins with excellent counts statistics before the peak in the 10 to 1000 keV flux.

As seen in Fig. 1, there is a clear trend in the individual detector’s light curves: the >20 MeV
Fermi Large Area Telescope (LAT) low-energy (LLTE) (14, 15) light curve peaks before the GBM trigger time (T0), whereas the GBM bismuth germanate (BGO) detector #1 (300 keV to 45 MeV) and sodium iodide (NaI) detector #6 (8 to 300 keV) peak at successively later times. To quantify this, we performed an energy-dependent pulse lag analysis using a Discrete Cross Correlation Function (DCCF) and obtained the time lags (16) between the highest energy LAT LLTE light curve and light curves at several selected energy ranges in the GBM NaI and BGO detectors (Fig. 1, inset). We find good agreement between the expected lag behavior and the pulse width model \( W(E) \propto E^{\alpha} \) (17), obtaining a fitted value for \( \alpha = -0.27 \pm 0.03 \) (18). This model was previously fit to 400 pulses from 41 BATSE GRBs (17); an average value of \( \alpha = -0.41 \) was found. Synchrotron shock model simulations made by Daigne and Mochkovitch (19) found \( \alpha \sim -0.4 \) for pulses of 2- to 10-s duration, but \( \alpha \approx -0.2 \) for pulses of 0.1 to 1 s. Three LAT photons with energies greater than 100 MeV are clustered in coincidence with the LLTE peak, and so may arise by the same mechanism.

Although most GRB spectra are well fit by a smoothly joined broken power-law function \( E_{\text{peak}}(\alpha, \beta) \), whereas the GBM bismuth germanate (BGO) detector #1 (300 keV to 45 MeV) synchrotron function. We present two separate time-resolved spectral analyses for the first 2.5 s of GRB 130427A, with comparable goodness of fit: the Burgess et al. synchrotron function plus blackbody, and the Band function (18). A blackbody component is not required when the more flexible Band function alone is used. Although the time evolution of \( E_{\text{peak}}(\alpha, \beta) \) as determined by Band function fits is consistent with a single power law (with an index of \(-0.96 \pm 0.02\)), the evolution of the synchrotron peak energy is not (Fig. 2). A broken power-law fit is better constrained and shows a shallower decay before the pulse peak, with an index of \(-0.4 \pm 0.2\) during the rising phase and \(-1.17 \pm 0.05\) during the decaying phase and a fitted break time at \( T_0 + 0.28 \pm 0.08\) s, or \(-0.2\) s before the pulse peak in the 10- to 1000-kEV flux. Both fitted indices during the decay phase are consistent with the \( -1\) power-law index expected from standard fireball curvature effects (25, 26).

The shallower spectral peak decay index before the light curve decay phase has a natural explanation in the context of the pulse being driven by a shock between thick, colliding shells (19).

Two-component models including a thermal contribution (27) constrain the value of the photospheric radius using the blackbody flux and temperature \( (kT) \) (see table S1). Comparing with the flux of the dominant nonthermal spectral component then permits determination of the Lorentz factor at the photosphere \( (\Gamma_{\text{iso}}) \) (28). As shown in Fig. 3, the minimum value of the photospheric bulk Lorentz factor \( \Gamma_{\text{iso}} \) starts out at 500 and monotonically decreases to \< 100 over the duration of the pulse (similar to behavior observed in GRB 110721A) (29). Internal shocks require higher Lorentz factors at later times. However, this might still be consistent with the monotonically decreasing \( \Gamma_{\text{iso}} \) if the outflowing shell that produces this photospheric component produced the nonthermal triggering pulse by colliding with a slower and slightly earlier ejected shell that did not produce detectable photospheric emission. Otherwise, the observed behavior would favor magnetic recombination models or mini-jets (30, 31), which abandon a simple spherical geometry.

Using the measured redshift of \( z = 0.34 \) (32), the host rest-frame luminosity and synchrotron peak energies are calculated, and the decay-phase apparent isotropic luminosity \( L_{\text{iso}} \) correlation is fit with a power-law index of \( 1.43 \pm 0.04 \) (Fig. 4). A theoretical analysis of high-latitude curvature radiation production in relativistic shell collisions of spherical blast waves shows a \( L_{\text{iso}} \) during the decay phase of a pulse (25, 26), contrary to the behavior shown in Fig. 4. In a picture of an expanding fluid element rather than a colliding shell, synchrotron emission by electrons with characteristic energy \( \gamma_e \) obeys the relations \( E_{\text{peak}}(\alpha, \beta) \ll \gamma_e^{\Gamma_{\text{iso}}B_{\text{iso}}^2} = \Gamma_{\text{iso}}B_{\text{iso}}^2 \), for \( \gamma_e \) and \( B_{\text{iso}} \) both in the jet frame. In the optically thin coasting phase of the outflow, the bulk Lorentz factor \( \Gamma_{\text{iso}} \)
is constant. Naively assuming that the magnetic flux is frozen in the flow (\(BR^2 \propto \text{const.}\) in the comoving frame, where \(R\) is the comoving emission region radius), then adiabatic losses of the electrons imply \(\gamma_e \propto R^{3/2}\). A short calculation then gives \(L \propto E_{\text{peak}}^{3/2}\), which is consistent with the 1.43 index derived from the data. A constant expansion velocity \(dR/dt\) scenario predicts, however, \(E_{\text{peak}} \propto R^{-4} \propto t^{-4}\). Other jet-wind assumptions...

**Fig. 1. The first 3 s of GRB 130427A.** Shown are composite light curves for the three Fermi detector types. Green, GBM NaI #6 (10 to 300 keV); blue, GBM BGO #1 (300 keV to 45 MeV); red, LAT LLE (>20 MeV). Each curve has been normalized so that their peak intensities match. High-probability LAT photons >100 MeV are indicated by circles (right axis, energy in MeV). (Inset) Lag analysis of the triggering pulse of GRB 130427A. Time lag \(\tau\) (filled symbols) as determined by the DCCF analysis between the (10 to 100 MeV) LLE light curve and selected energy bands of the NaI (green) and BGO (blue) light curves. Also displayed are fitted pulse widths as a function of energy \(W(E)\) (hollow symbols, in seconds) for several energy bands. The two dashed lines represent: 1, the best-fit power-law model (\(\chi^2\) of 5.6 for 9 degrees of freedom) for \(W(E)\) (black), and 2, the expected dependence of the time lag \(\tau\) as a function of energy (red), assuming the same power-law index as in 1.

**Fig. 2. The fitted Band function \(E_{\text{peak}}\) (blue) and synchrotron peak energies (red) as a function of time.** The times are referenced from when the LLE light curve peaks 0.1 s before the trigger. A broken power-law fit to the red points is indicated by a dashed line (early time decay index of \(-0.4 \pm 0.2\), with a break at 0.38 ± 0.08 s, breaking to an index of \(-1.17 \pm 0.05\) with a \(\chi^2 = 28\) for 22 degrees of freedom). We also show the Band function \(E_{\text{peak}}\) values for the same time intervals with a single fitted power-law index (\(-0.96 \pm 0.02\) with a \(\chi^2\) of 19 for 24 degrees of freedom).
yield different correlations—for example, for the deceleration epoch where $dV/dt < 0$ or for radial field evolution appropriate for jet cores.

The isolated initial pulse of GRB 130427A is apparently unmodified by preceding engine activity or nascent external shock emission. Our analysis shows that there is good agreement between the pulse width as a function of energy and the expected lag, that the characteristic energy has roughly a −1 power-law decay with time during the decaying phase, that the temperature of the blackbody component implies a photospheric radius incompatible with the internal shock radius, and that the apparent isotropic luminosity is related to the 3/2 power of the characteristic energy. It is a challenge to explain all these behaviors simultaneously.

Bright Lights

Gamma-ray bursts (GRBs), bright flashes of gamma-ray light, are thought to be associated with the collapse of massive stars. GRB 130427A was detected on 27 April 2013, and it had the longest gamma-ray duration and one of the largest isotropic energy releases observed to date (see the Perspective by Fynbo). Ackermann et al. (p. 42, published online 21 November) report data obtained with the Fermi Gamma-Ray Space Telescope, which reveal a high-energy spectral component that cannot be accounted for by the standard external shock synchrotron radiation model. Vestrand et al. (p. 38, published online 21 November) report the detection of an extremely bright flash of visible light and unexpected similarities between the variations of optical light and the highest-energy gamma rays that indicate a common origin. A detailed analysis of the first pulse of GRB 130427A by Preece et al. (p. 51, published online 21 November) suggests that existing models cannot explain all the observed spectral and temporal behaviors simultaneously. Maselli et al. (p. 48, published online 21 November) present x-ray and optical light curves of the burst’s prompt emission as well as of its afterglow as recorded by the Swift satellite and a range of ground-based telescopes.
