Searches for long-lived charged particles in pp collisions at $\sqrt{s} = 7$ and 8 TeV

The CMS collaboration

E-mail: cms-publication-committee-chair@cern.ch

Abstract: Results of searches for heavy stable charged particles produced in pp collisions at $\sqrt{s} = 7$ and 8 TeV are presented corresponding to an integrated luminosity of 5.0 fb$^{-1}$ and 18.8 fb$^{-1}$, respectively. Data collected with the CMS detector are used to study the momentum, energy deposition, and time-of-flight of signal candidates. Leptons with an electric charge between $e/3$ and $8e$, as well as bound states that can undergo charge exchange with the detector material, are studied. Analysis results are presented for various combinations of signatures in the inner tracker only, inner tracker and muon detector, and muon detector only. Detector signatures utilized are long time-of-flight to the outer muon system and anomalously high (or low) energy deposition in the inner tracker. The data are consistent with the expected background, and upper limits are set on the production cross section of long-lived gluinos, scalar top quarks, and scalar $\tau$ leptons, as well as pair produced long-lived leptons. Corresponding lower mass limits, ranging up to 1322 GeV/$c^2$ for gluinos, are the most stringent to date.

Keywords: Hadron-Hadron Scattering

ArXiv ePrint: 1305.0491
1 Introduction

Many extensions of the standard model (SM) include heavy, long-lived, charged particles that have speed $v$ significantly less than the speed of light $c$ [1–3] or charge $Q$ not equal to the elementary positive or negative charge $\pm 1e$ [4–8], or both. With lifetimes greater than a few nanoseconds, these particles can travel distances comparable to the size of modern detectors and thus appear to be stable. These particles, generically referred to as heavy stable charged particles (HSCP), can be singly charged ($|Q| = 1e$), fractionally charged ($|Q| < 1e$), or multiply charged ($|Q| > 1e$). Without dedicated searches, HSCPs may be misidentified or even completely missed, as particle identification algorithms at hadron collider experiments generally assume signatures appropriate for SM particles, e.g., $v \approx c$ and $Q = 0$ or $\pm 1e$. Additionally, some HSCPs may combine with SM particles to form composite objects. Interactions of these composite objects with the detector may change their constituents and possibly their electric charge, further limiting the ability of standard algorithms to identify them.

For HSCP masses greater than 100 GeV/c$^2$, a significant fraction of particles produced at the Large Hadron Collider (LHC) have $\beta$ ($\equiv v/c$) values less than 0.9. These HSCPs can be identified by their longer time-of-flight (TOF) to outer detectors or their anomalous energy loss ($dE/dx$). The $dE/dx$ of a particle depends on both its electric charge (varying as
Figure 1. Distribution of $I_h$, a $dE/dx$ estimator that is defined in section 3.1, versus particle momentum for $\sqrt{s} = 8$ TeV data (left) and also including MC simulated HSCP candidates of different charges (right). Tracks with $2.8 \leq I_h \leq 3.0 \text{MeV/cm}$ are excluded by preselection requirements, as discussed in section 4.

$Q^2$) and its $\beta$. The dependence of $dE/dx$ on these variables is described by the Bethe-Bloch formula [9]. This dependence can be seen in figure 1, which shows a $dE/dx$ estimate versus momentum for tracks from data and Monte Carlo (MC) simulations of HSCP signals with various charges. In the momentum range of interest (10–1000 GeV/c), SM charged particles have a relatively flat ionization energy loss and $\beta$ values very close to one. Searching for candidates with long time-of-flight or large $dE/dx$ gives sensitivity to massive particles with $|Q| = 1e$, particles with $|Q| > 1e$, and low-momentum particles with $|Q| < 1e$. On the other hand, searching for candidates with lower $dE/dx$ yields sensitivity to high-momentum particles with $|Q| < 1e$.

Previous collider searches for HSCPs have been performed at LEP [10–13], HERA [14], the Tevatron [15–18], and the LHC [19–26]. The results from such searches have placed important bounds on beyond the standard model (BSM) theories [27, 28], such as lower limits on the mass of gluinos, scalar top quarks (stops), and pair-produced scalar $\tau$ leptons (staus) at 1098, 737, and 223 GeV/c$^2$, respectively. Presented here are several searches for singly, fractionally, and multiply charged HSCPs using data collected with the Compact Muon Solenoid (CMS) detector during the 2011 ($\sqrt{s} = 7$ TeV, 5.0 fb$^{-1}$) and 2012 ($\sqrt{s} = 8$ TeV, 18.8 fb$^{-1}$) data taking periods.

2 Signal benchmarks

The searches presented here are sensitive to a wide variety of signals of new charged massive particles. Several BSM models are used to benchmark the sensitivity. The HSCPs can be classified as either lepton-like or hadron-like. Lepton-like HSCPs interact primarily through the electromagnetic force, while hadron-like HSCPs additionally interact through the strong
force and form bound states with SM quarks (or gluons) called $R$-hadrons [29]. The $R$-hadrons can be charged or neutral. Strong interactions between the SM quarks and detector material increase energy loss and can lead to charge exchange, e.g., conversion of charged $R$-hadrons into neutral ones (and vice-versa). There is some uncertainty in the modeling of $R$-hadrons’ strong interactions with detector material. For this analysis, two separate models are considered: (1) the model described in refs. [30, 31], referred to as the cloud model, and (2) a model in which any strong interaction results in a neutral $R$-hadron [32], referred to as the charge-suppressed model. The cloud model envisions the $R$-hadron as composed of a spectator HSCP surrounded by a cloud of colored, light constituents. The charge-suppressed model results in essentially all $R$-hadrons being neutral by the time they enter the muon system. For each of the models considered, particle interactions with the CMS apparatus and detector response are simulated using GEANT4 v9.2 [33, 34]. To produce the effect of multiple interactions per bunch crossing (pileup), simulated minimum bias events are overlaid with the primary collision.

The minimal gauge-mediated supersymmetry breaking (GMSB) model [35] predicts the gravitino to be the lightest supersymmetric particle (LSP) and allows for the next-to-lightest supersymmetric particle (NLSP) to be long-lived because of the weakness of the gravitational coupling, which governs the decay of the NLSP to the LSP. For this analysis the NLSP is taken to be a lepton-like stau ($\tilde{\tau}_1$) with an assumed lifetime that exceeds the time-of-flight through the CMS detector. For $\sqrt{s} = 7$ (8) TeV simulation, PYTHIA v6.422 (v6.426) [36] is used to model both Drell-Yan production of a $\tilde{\tau}_1$ pair (direct pair-production) and production of heavier supersymmetric particles whose decay chains lead to indirect stau production. Events with $\tilde{\tau}_1$ masses in the range 100–557 GeV/c² are generated using line 7 of the "Snowmass Points and Slopes" benchmarks [37]. They correspond to $N = 3$ chiral SU(5) multiplets added to the theory at a scale $F$ from 60 to 360 TeV [35] depending on the $\tilde{\tau}_1$ mass, and an effective supersymmetry-breaking scale of $\Lambda = F/2$. All points have a value of 10 for the ratio of neutral Higgs field vacuum expectation values ($\tan\beta$), a positive sign for the Higgs-Higgsino mass parameter ($\text{sgn}(\mu)$), and a value of $10^4$ for the ratio of the gravitino mass to the value it would have if the only supersymmetry-breaking scale were that in the messenger sector ($\epsilon_{\text{grav}}$). The particle mass spectrum and the decay table were produced with the program ISASUGRA version 7.69 [38]. Theoretical production cross sections ($\sigma_{\text{th}}$) for staus are calculated at next-to-leading order (NLO) with PROSPINO v2.1 [39]. Compared to the previous publication [24], the theoretical NLO cross section used for the indirect production of staus also includes processes involving pairs of neutralinos/charginos.

$R$-hadron signals from gluino ($\tilde{g}$) and scalar top ($\tilde{t}_1$) pair production are studied using PYTHIA v6.442 (v8.153) [36, 40] for $\sqrt{s} = 7$ (8) TeV generation. Stop pair production is modeled for masses in the range 100–1000 GeV/c². For $\tilde{g}$ production, split supersymmetry [41, 42] is modeled by setting the squark masses to greater than 10 TeV/c² and generating $\tilde{g}$ masses of 300–1500 GeV/c². The fraction $f$ of gluinos hadronizing into $\tilde{g}$-gluon bound states is unknown. These neutral states would not leave a track in the inner detectors. Therefore, several scenarios are considered for the singly charged analysis: $f = 0.1, 0.5, \text{and } 1.0$. In the extreme case where $f = 1.0$, $R$-hadrons are always neutral in the inner tracker, but a fraction of them may interact with the detector material and be electrically...
charged during their passage through the muon system. Gluino and scalar top pair production cross sections are calculated at NLO plus next-to-leading logarithmic (NLL) accuracy with prospino v2.1 [43–50].

The last of the signal samples studied is the modified Drell-Yan production of long-lived leptons. In this scenario, new massive spin-1/2 particles may have an electric charge different than $|Q| = 1e$ and are neutral under $SU(3)_C$ and $SU(2)_L$; therefore they couple only to the photon and the Z boson via $U(1)$ couplings [51]. Signal samples are simulated using PYTHIA v6.422 (v6.426) [36] for $\sqrt{s} = 7 \ (8)$ TeV. The analysis uses simulations of $|Q| = e/3$ and $2e/3$ for masses of 100–600 GeV/$c^2$, of $|Q|$ ranging from 1e to 6e for masses of 100–1000 GeV/$c^2$, and of $|Q| = 7e$ and 8e for masses of 200–1000 GeV/$c^2$.

The CTEQ6L1 parton distribution functions (PDF) [52] are used for the sample generation.

3 The CMS detector

The CMS experiment uses a right-handed coordinate system, with the origin at the nominal interaction point, the $x$ axis pointing to the center of the LHC ring, the $y$ axis pointing up (perpendicular to the plane of the LHC ring), and the $z$ axis along the counterclockwise-beam direction. The polar angle $\theta$ is measured from the positive $z$ axis and the azimuthal angle $\phi$ in the $x$-$y$ plane. The pseudorapidity is given by $\eta = -\ln[\tan(\theta/2)]$.

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter. Within the field volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter, and a brass and scintillator hadron calorimeter. Muons are measured in gas-ionization detectors embedded in the steel flux-return yoke of the magnet. Extensive forward calorimetry complements the coverage provided by the barrel and endcap detectors. The inner tracker measures charged particles within the pseudorapidity range $|\eta| < 2.5$. It consists of 1440 silicon pixel and 15 148 silicon strip detector modules and is located in the 3.8 T field of the solenoid. The inner tracker provides a transverse momentum ($p_T$) resolution of about 1.5% for 100 GeV/c particles. Muons are measured in the pseudorapidity range $|\eta| < 2.4$, with detection planes made using three technologies: drift tubes (DT), cathode strip chambers (CSC), and resistive plate chambers (RPC). The muon system extends out to eleven meters from the interaction point in the $z$ direction and seven meters radially. Matching tracks in the muon system to tracks measured in the silicon tracker results in a transverse momentum resolution between 1 and 5%, for $p_T$ values up to 1 TeV/c. The first level (L1) of the CMS trigger system, composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events of interest. The high level trigger (HLT) processor farm further decreases the event rate from around 100 kHz to around 300 Hz for data storage. A more detailed description of the CMS detector can be found in ref. [53].

3.1 The $dE/dx$ measurements

As in ref. [19], $dE/dx$ for a track is estimated as:

$$I_h = \left( \frac{1}{N} \sum_i c_i^{-2} \right)^{-1/2}, \quad (3.1)$$
where \( N \) is the number of measurements in the silicon-strip detectors and \( c_i \) is the energy loss per unit path length in the sensitive part of the silicon detector of the \( i \)th measurement; \( I_h \) has units MeV/cm. In addition, two modified versions of the Smirnov-Cramer-von Mises [54, 55] discriminator, \( I_{as}(I'_{as}) \), are used to separate SM particles from candidates with large (small) \( dE/dx \). The discriminator is given by:

\[
I_{as}^{(i)} = \frac{3}{N} \times \left( \frac{1}{12N} + \sum_{i=1}^{N} \left[ P_{i}^{(i)} \times \left( P_{i}^{(i)} - \frac{2i - 1}{2N} \right)^2 \right] \right),
\]

where \( P_{i} \) (\( P'_{i} \)) is the probability for a minimum ionizing particle (MIP) to produce a charge smaller (larger) or equal to that of the \( i \)th measurement for the observed path length in the detector, and the sum is over the measurements ordered in terms of increasing \( P_{i}^{(i)} \).

As in ref. [19], the mass of a \( |Q| = 1e \) candidate particle is calculated based on the relationship:

\[
I_{h} = K \frac{m^2}{p^2} + C,
\]

where the empirical parameters \( K = 2.559 \pm 0.001 \) MeV \( \cdot c^2/cm \) and \( C = 2.772 \pm 0.001 \) MeV/cm are determined from data using a sample of low-momentum protons in a minimum-bias dataset.

The number of silicon-strip measurements associated with a track, 15 on average, is sufficient to ensure good \( dE/dx \) and mass resolutions.

### 3.2 Time-of-flight measurements

As in ref. [24], the time-of-flight to the muon system can be used to discriminate between \( \beta \approx 1 \) particles and slower candidates. The measured time difference (\( \delta t \)) of a hit relative to that expected for a \( \beta = 1 \) particle can be used to determine the particle \( 1/\beta \) via the equation:

\[
1/\beta = 1 + \frac{c\delta t}{L},
\]

where \( L \) is the flight distance from the interaction point. The track \( 1/\beta \) value is calculated as the weighted average of the \( 1/\beta \) measurements from the DT and CSC hits associated with the track. A description of how the DT and CSC systems measure the time of hits is given below.

As tubes in consecutive layers of DT chambers are staggered by half a tube, a typical track passes alternatively to the left and to the right of the sensitive wires in consecutive layers. The position of hits is inferred from the drift time of the ionization electrons assuming the hits come from a prompt muon. For a late arriving HSCP, the delay will result in a longer drift time being attributed, so hits drifting left will be to the right of their true position while hits drifting right will be to the left. The DT measurement of \( \delta t \) then comes from the residuals of a straight line fit to the track hits in the chamber. Only phi-projections from the DT chambers are used for this purpose. The weight for the \( i \)th DT measurement is given by:

\[
w_i = \frac{(n-2)}{n} \frac{L_i^2}{c^2\sigma_{DT}^2},
\]

\( n \) is the number of measurements in the silicon-strip detectors and \( L_i \) is the path length from the interaction point to the i-th hit in the DT layer.
where \( n \) is the number of \( \phi \) projection measurements found in the chamber from which the measurement comes and \( \sigma_{DT} = 3 \) ns is the time resolution of the DT measurements. The factor \((n - 2)/n\) accounts for the fact that residuals are computed using two parameters of a straight line determined from the same \( n \) measurements (the minimum number of hits in a DT chamber needed for a residual calculation is \( n = 3 \)). Particles passing through the DTs have on average 16 time measurements.

The CSC measurement of \( \delta_t \) is found by measuring the arrival time of the signals from both the cathode strips and anode wires with respect to the time expected for prompt muons. The weight for the \( i \)th CSC measurement is given by:

\[
w_i = \frac{L^2_i}{c^2 \sigma^2_i},
\]

where \( \sigma_i \), the measured time resolution, is 7.0 ns for cathode strip measurements and 8.6 ns for anode wire measurements. Particles passing through the CSCs have on average 30 time measurements, where cathode strip and anode wire measurements are counted separately.

The uncertainty \((\sigma_{1/\beta})\) on \( 1/\beta \) for the track is found via the equation:

\[
\sigma_{1/\beta} = \sqrt{\sum_{i=1}^{N} \left(1/\beta_i - \overline{1/\beta}\right)^2 \times w_i},
\]

where \( \overline{1/\beta} \) is the average \( 1/\beta \) of the track and \( N \) is the number of measurements associated with the track.

Several factors including the intrinsic time resolution of the subsystems, the typical number of measurements per track, and the distance from the interaction point lead to a resolution of about 0.065 for \( 1/\beta \) in both the DT and CSC subsystems over the full \( \eta \) range.

## 4 Data selection

Multiple search strategies are used to separate signal from background depending on the nature of the HSCP under investigation.

- For singly charged HSCPs,
  - the “tracker+TOF” analysis requires tracks to be reconstructed in the inner tracker and the muon system,
  - the “tracker-only” analysis only requires tracks to be reconstructed in the inner tracker, and
  - the “muon-only” analysis only requires tracks to be reconstructed in the muon system.
- For fractionally charged HSCPs, the “fractionally charged” \((|Q| < 1e)\) analysis only requires tracks to be reconstructed in the inner tracker and to have a \( dE/dx \) smaller than SM particles.
For multiply charged HSCPs, the “multiply charged” (|Q| > 1e) analysis requires tracks to be reconstructed in the inner tracker and the muon system. The analysis is optimized for much larger ionization in the detector compared to the tracker+TOF analysis.

HSCP signal events have unique characteristics. For each analysis, the primary background arises from SM particles with random fluctuations in energy deposition/timing or mis-measurement of the energy, timing, or momentum.

The tracker-only and muon-only cases allow for the possibility of charge flipping (charged to neutral or vice versa) within the calorimeter or tracker material. The muon-only analysis is the first CMS search that does not require an HSCP to be charged in the inner tracker. The singly, multiply, and fractionally charged analyses feature different selections, background estimates, and systematic uncertainties. The preselection requirements for the analyses are described below.

All events must pass a trigger requiring either the reconstruction of (i) a muon with high \( p_T \) or (ii) large missing transverse energy (\( E_{\text{miss}}^T \)) defined as the magnitude of the vectorial sum of the transverse momenta of all particles reconstructed by an online particle-flow algorithm [56] at the HLT.

The L1 muon trigger allows for late arriving particles (such as slow moving HSCPs) by accepting tracks that produce signals in the RPCs within either the 25 ns time window corresponding to the interaction bunch crossing or the following 25 ns time window. For the data used in this analysis, the second 25 ns time window is empty of proton-proton collisions because of the 50 ns LHC bunch spacing during the 2011 and 2012 operation.

Triggering on \( E_{\text{miss}}^T \) allows for some recovery of events with hadron-like HSCPs in which none of the R-hadrons in the event are charged in both the inner tracker and the muon system. The \( E_{\text{miss}}^T \) in the event arises because the particle-flow algorithm rejects tracks not consistent with a SM particle. This rejection includes tracks reconstructed only in the inner tracker with a track \( p_T \) much greater than the matched energy deposited in the calorimeter [57] as would be the case for R-hadrons becoming neutral in the calorimeter, and tracks reconstructed only in the muon system as would be the case for R-hadrons that are initially neutral. Thus, in both cases, only the energy these HSCPs deposit in the calorimeter, roughly 10–20 GeV, will be included in the \( E_{\text{miss}}^T \) calculation. In events in which no HSCPs are reconstructed as muon candidates, significant \( E_{\text{miss}}^T \) will result if the vector sum of the HSCPs’ momenta is large. The \( E_{\text{miss}}^T \) trigger will collect these events, allowing for sensitivity to HSCP without a muon-like signature.

For all the analyses, the muon trigger requires \( p_T > 40 \) GeV/c measured in the inner tracker and the \( E_{\text{miss}}^T \) trigger requires \( E_{\text{miss}}^T > 150 \) GeV at the HLT. The muon-only analysis uses the same two triggers, and additionally a third trigger that requires both a reconstructed muon segment with \( p_T > 70 \) GeV/c (measured using only the muon system) and \( E_{\text{miss}}^T > 55 \) GeV. For the first part of the 2012 data (corresponding to an integrated luminosity of 700 pb\(^{-1}\)), the requirement was \( E_{\text{miss}}^T > 65 \) GeV. Using multiple triggers in all of the analyses allows for increased sensitivity to HSCP candidates that arrive late in the muon system and to hadron-like HSCPs that are sometimes charged in only one of the
inner tracker and muon system and sometimes charged in both. The muon-only analysis uses only $\sqrt{s} = 8\text{ TeV}$ data as the necessary triggers were not available in 2011.

For the tracker-only analysis, all events are required to have a track candidate in the region $|\eta| < 2.1$ with $p_T > 45\text{ GeV/c}$ (as measured in the inner tracker). In addition, a relative uncertainty in $p_T$ ($\sigma_{p_T}/p_T$) less than 0.25 and a track fit $\chi^2$ per number of degrees of freedom ($n_d$) less than 5 is required. Furthermore, the magnitudes of the longitudinal ($d_z$) and transverse ($d_{xy}$) impact parameters are both required to be less than 0.5 cm. The impact parameters $d_z$ and $d_{xy}$ are both defined with respect to the primary vertex that yields the smallest $|d_z|$ for the candidate track. The requirements on the impact parameters are very loose compared with the resolutions for tracks ($\sigma(d_{xy,z}) < 0.1\text{ cm}$) in the inner tracker. Candidates must pass isolation requirements in the tracker and calorimeter. The tracker isolation requirement is $\Sigma p_T < 50\text{ GeV/c}$ where the sum is over all tracks (except the candidate’s track) within a cone about the candidate track $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} < 0.3$ radians. The calorimeter isolation requirement is $E/p < 0.3$ where $E$ is the sum of energy deposited in the calorimeter towers within $\Delta R < 0.3$ (including the candidate’s energy deposit) and $p$ is the candidate track momentum reconstructed from the inner tracker. Candidates must have at least two measurements in the silicon pixel detector and at least eight measurements in the combination of the silicon strip and pixel detectors. In addition, there must be measurements in at least 80% of the silicon layers between the first and last measurements on the track. To reduce the rate of contamination from clusters with large energy deposition due to overlapping tracks, a "cleaning" procedure is applied to remove clusters in the silicon strip tracker that are not consistent with passage of only one charged particle (e.g., a narrow cluster with most of the energy deposited in one or two strips). After cluster cleaning, there must be at least six measurements in the silicon strip detector that are used for the $dE/dx$ calculation. Finally, $I_h > 3\text{ MeV/cm}$ is required.

The tracker+TOF analysis applies the same criteria, but additionally requires a reconstructed muon matched to a track in the inner detectors. At least eight independent time measurements are needed for the TOF computation. Finally, $1/\beta > 1$ and $\sigma_{1/\beta} < 0.07$ are required.

The muon-only analysis uses separate criteria that include requiring a reconstructed track in the muon system with $p_T > 80\text{ GeV/c}$ within $|\eta| < 2.1$. The relative resolution in $p_T$ is approximately 10% in the barrel region and approaches 30% for $|\eta| > 1.8$ [58]. However, charge flipping by $R$-hadrons can lead to an overestimate of $p_T$. The effect is more pronounced for gluinos, where all of the electric charge comes from SM quarks. The measured curvature in the muon system for gluinos is 60–70% smaller than would be expected for a muon with the same transverse momentum. The candidate track must have measurements in two or more DT or CSC stations, and $|d_z|$ and $|d_{xy}| < 15\text{ cm}$ (calculated using tracks from the muon system and measured relative to the nominal beam spot position rather than to the reconstructed vertex). The requirements on $|d_z|$ and $|d_{xy}|$ are approximately 90% and 95% efficient for prompt tracks, respectively. HSCPs are pair produced and often back-to-back in $\phi$ but not in $\eta$ because the collision is in general boosted along the $z$-axis. On the other hand, cosmic ray muons passing close to the interaction point would pass through the top and bottom halves of CMS, potentially giving the appearance of two tracks.
back-to-back in both $\phi$ and $\eta$. Often only one of these legs will be reconstructed as a track while the other will leave only a muon segment (an incomplete track) in the detector. To reject cosmic ray muons, candidates are removed if there is a muon segment both with $\eta$ within $\pm 0.1$ of $-\eta_{\text{cand}}$, where $\eta_{\text{cand}}$ is the pseudorapidity of the HSCP candidate, and with $|\delta \phi| > 0.3$ radians, where $\delta \phi$ is the difference in $\phi$ between the candidate and the muon segment. The $|\delta \phi|$ requirement prevents candidates with small $|\eta|$ from being rejected by their proximity to their own muon segments. Additionally, candidates compatible with vertically downward cosmic ray muons, $1.2 < |\phi| < 1.9$ radians, are rejected. To reject muons from adjacent beam crossings, tracks are removed if their time leaving the interaction point as measured by the muon system is within $\pm 5$ ns of a different LHC beam crossing. This veto makes the background from muons from such crossings negligible while removing very little signal. Finally, the same quality requirements used in the tracker+TOF analysis are applied in the muon-only $1/\beta$ measurement.

The fractionally charged search uses the same preselection criteria as the tracker-only analysis except that $I_h$ is required to be $< 2.8 \text{ MeV/cm}$. An additional veto on cosmic ray muons rejects candidates if a track with $p_T > 40 \text{ GeV/c}$ is found on the opposite side of the detector ($\Delta R > \pi - 0.3$).

The multiply charged particle search uses the same preselection as the tracker+TOF analysis except that the $E/p$ selection is removed. Furthermore, given that a multiply charged particle might have a cluster shape different from that of a $|Q| = 1e$ particle, the cluster cleaning procedure is not applied for the multiply charged analysis.

The preselection criteria applied on the inner tracker track for the analyses are summarized in table 1 while the criteria on the muon system track are summarized in table 2.

5 Background prediction

Candidates passing the preselection criteria (section 4) are subject to two (or three) additional selection criteria to further improve the signal-to-background ratio. For all of the analyses, results are based upon a comparison of the number of candidates passing the final section criteria with the number of background events estimated from the numbers of events that fail combinations of the criteria.

The background expectation in the signal region, $D$, is estimated as $D = BC/A$, where $B$ ($C$) is the number of candidates that fail the first (second) criteria but pass the other one and $A$ is the number of candidates that fail both criteria. The method works if the probability for a background candidate to pass one of the criteria is not correlated with whether it passes the other criteria. The lack of strong correlation between the selection criteria is evident in figure 2. Tests of the background prediction (described below) are used to quantify any residual effect and to calculate the systematic error in the background estimate. All tracks passing the preselection enter either the signal region $D$ or one of the control regions that is used for the background prediction.

For the tracker-only analysis, the two chosen criteria are $p_T$ and $I_{as}$. Threshold values ($p_T > 70 \text{ GeV/c}$ and $I_{as} > 0.4$) are fixed such that failing candidates passing only $p_T$ ($I_{as}$) fall into the $B$ ($C$) regions. The $B$ ($C$) candidates are then used to form a binned
Table 1. Preselection criteria on the inner tracker track used in the various analyses as defined in the text.

| Parameter                      | \(|Q| < 1\) | tracker+TOF | tracker-only | \(|Q| > 1\) |

probability density function in \(I_h(p)\) such that, using the mass determination (eq. (3.3)), the full mass spectrum of the background in the signal region \(D\) can be predicted. The \(\eta\) distribution of candidates at low dE/dx differs from the distribution of the candidates at high dE/dx. To correct for this effect, events in the \(C\) region are weighted such that the \(\eta\) distribution matches that in the \(B\) region.

For the tracker+TOF analysis, three criteria are used, \(p_T\), \(I_{as}\), and \(1/\beta\), creating eight regions labeled \(A\) through \(H\). The final threshold values are selected to be \(p_T > 70\) GeV/c,
$I_{as} > 0.125$, and $1/\beta > 1.225$. Region $D$ represents the signal region, with events passing all three criteria. The candidates in the $A$, $F$, and $G$ regions pass only the $1/\beta$, $I_{as}$, and $p_T$ criteria, respectively, while the candidates in the $B$, $C$, and $H$ regions fail only the $p_T$, $I_{as}$, and $1/\beta$ criteria, respectively. The $E$ region fails all three criteria. The background estimate can be made from several different combinations of these regions. The combination $D = AGF/E^2$ is used because it yields the smallest statistical uncertainty. Similar to the tracker-only analysis, events in the $G$ region are reweighted to match the $\eta$ distribution in the $B$ region. From a consideration of the observed spread in background estimates from the other combinations, a 20% systematic uncertainty is assigned to the background estimate. The 20% systematic uncertainty is also assigned to the background estimate for the tracker-only analysis.

In order to check the background prediction, loose selection samples, which would be dominated by background tracks, are used for the tracker-only and tracker+TOF analyses. The loose selection sample for the tracker-only analysis is defined as $p_T > 50\,\text{GeV}/c$ and $I_{as} > 0.10$. The loose selection sample for the tracker+TOF analysis is defined as $p_T > 50\,\text{GeV}/c$, $I_{as} > 0.05$, and $1/\beta > 1.05$. Figure 3 shows the observed and predicted mass spectra for these samples.

The muon-only analysis uses the $p_T$ and $1/\beta$ criteria for the $ABCD$ method. The final selections are $p_T > 230\,\text{GeV}/c$ and $1/\beta > 1.4$. It has been found that these variables are correlated with $|\eta|$ and with the number of muon stations used to fit the candidate. Therefore, the background prediction is performed in six separate bins ($2/3/4$ muon stations in central ($|\eta| < 0.9$) and forward ($0.9 < |\eta| < 2.1$) regions). The final result is computed from a sum of these six bins. The systematic uncertainty in this background estimate is determined by defining four additional regions $A', B', C'$, and $D'$. Events in $B'$ ($A'$) pass (fail) the $p_T$ requirement, but with $0.8 < 1/\beta < 1.0$, while events in $D'$ ($C'$) pass (fail) the $p_T$ requirement with $1/\beta < 0.8$. Two complementary predictions now become possible, $D = CB'/A'$ and $D = CD'/C'$. From a consideration of the spread of the three estimates,
Figure 3. Observed and predicted mass spectra for candidates entering the tracker-only (left column) or tracker+TOF (right column) signal region for the loose selection. The expected distribution for a representative signal scaled to the integrated luminosity is shown as the shaded histogram. The top (bottom) row is for $\sqrt{s} = 7$ (8) TeV.

A systematic uncertainty of 20% is assigned to the background estimate for the muon-only analysis using this method.

The muon-only analysis also has background contributions from cosmic ray muons even after the previously mentioned cosmic ray muon veto requirements are applied. The number of cosmic ray muons expected to pass the selection criteria is determined by using the sideband region of $70 < |d_z| < 120$ cm. To increase the number of cosmic ray muons in the sideband region, the veto requirements are not applied here. To reduce the contamination in the sideband region due to muons from collisions, the tracks are required to not be reconstructed in the inner tracker. The number of tracks ($N$) in the sideband
with $1/\beta$ greater than the threshold is counted. To determine the ratio ($R_\mu$) of candidates in the signal region with respect to the sideband region, a pure cosmic ray sample is used. The sample is collected using a trigger requiring a track from the muon system with $p_T > 20\text{GeV}/c$, rejecting events within $\pm 50\text{ns}$ of a beam crossing and events triggered as beam halo. The cosmic ray muon contribution to the muon-only analysis signal region is determined as $N \times R_\mu$. A similar procedure is used to subtract the estimated cosmic ray muon contribution to the $A$, $B$, and $C$ regions prior to estimating the collision muon background in the $D$ region. The cosmic ray muon contribution to the signal region constitutes approximately 60% of the total expected background. The systematic uncertainty in the cosmic ray muon contribution is determined by comparing estimates using $|d_z|$ ranges of $30–50\text{cm}$, $50–70\text{cm}$, $70–120\text{cm}$, and $>120\text{cm}$. It is found to be 80%. Figure 4 shows the numbers of predicted and observed candidates in both the control region with $1/\beta < 1$ and the signal region for various $p_T$ and $1/\beta$ thresholds for the $\sqrt{s} = 8\text{TeV}$ data. The number of predicted events includes both the cosmic ray muon and collision muon contributions. Only statistical uncertainties are shown.

The multiply charged analysis uses the $I_{\text{as}}$ and $1/\beta$ criteria. Since the default track reconstruction code assumes $|Q| = 1e$ for $p_T$ determination, the transverse momentum for $|Q| > 1e$ particles is underestimated by a factor of $1e/|Q|$. Therefore $p_T$ is not used in the final selection. In addition, while $dE/dx$ scales as $Q^2$, the dynamic range of the silicon readout of individual strips saturates for energy losses $\approx 3$ times that of a $\beta \approx 1$, $|Q| = 1e$ particle. Since both the $p_T$ scaling and the $dE/dx$ saturation effects can bias the reconstructed mass to lower values (less separation from background), the reconstructed mass is not used for this analysis. Despite the saturation effect, $|Q| > 1e$ particles have a larger incompatibility of their $dE/dx$ measurements with the MIP hypothesis, increasing...
the separation power of the dE/dx discriminator for multiply charged particles, relative to that for $|Q| = 1e$ HSCPs. The systematic uncertainty in the background estimate for the multiply charged analysis is determined by the same method that is used for the collision muon background in the muon-only analysis except with $p_T$ changed to be $I_{as}$. The two complementary estimates from the $1/\beta < 1.0$ region lead to a 20% uncertainty. Figure 5 shows the numbers of predicted and observed candidates for various $I_{as}$ and $1/\beta$ thresholds. Only the statistical uncertainties are shown.

The fractionally charged analysis uses the same method to estimate the background as the tracker-only analysis, replacing the $I_{as}$ variable with $I'_{as}$ and not applying a mass requirement. The systematic uncertainty in the prediction is taken from the tracker+TOF analysis. In addition, the cosmic ray muon background is studied, since particles passing through the tracker not synchronized with the LHC clock often produce tracker hits with low energy readout. The cosmic ray muon background is found to be small and a 50% uncertainty is assigned to this prediction. The numbers of predicted and observed candidates for various $p_T$ and $I_{as}$ thresholds can be seen in figure 6. Only the statistical uncertainties are shown.

For each analysis, fixed selections on the appropriate set of $I_{as}$, $I'_{as}$, $p_T$, and $1/\beta$ are used to define the final signal region (and the regions for the background prediction). These values are chosen to give discovery potential over the signal mass regions of interest. For the tracker-only and tracker+TOF analyses, an additional requirement on the reconstructed mass is applied. The mass requirement depends upon the HSCP signal. For a given model and HSCP mass, the range is $M_{reco} - 2\sigma$ to $2\text{TeV}/c^2$ where $M_{reco}$ is the average reconstructed mass for the given HSCP mass and $\sigma$ is the expected resolution. Both $M_{reco}$ and $\sigma$ are determined from simulation.
Figure 6. Observed and predicted numbers of tracks as a function of the $l'_{as}$ threshold for two different $p_T$ thresholds at $\sqrt{s} = 7$ TeV (left) and 8 TeV (right) for the fractionally charged analysis. Only statistical uncertainties are shown.

Table 3. Results of the final selections for the predicted background and the observed numbers of events. The uncertainties include both statistical and systematic contributions.

Table 3 lists the final selection criteria, the predicted numbers of background events, and the numbers of events observed in the signal region. Agreement between prediction and observation is seen over the full range of analyses. Figure 7 shows the observed and predicted mass distributions for the tracker-only and tracker+TOF analyses with the tight selection. The bump at lower mass values expected from the signal MC is due to the saturation of the strip electronic readout.
Figure 7. Observed and predicted mass spectra for candidates entering the tracker-only (left column) or tracker+TOF (right column) signal region for the tight selection. The expected distribution for a representative signal scaled to the integrated luminosity is shown as the shaded histogram. The top (bottom) row is for $\sqrt{s} = 7$ (8) TeV.

6 Systematic uncertainties

The sources of systematic uncertainty include those related to the integrated luminosity, the background prediction, and the signal acceptance. The uncertainty in the integrated luminosity is 2.2% (4.4%) at $\sqrt{s} = 7$ (8) TeV [59, 60]. The uncertainties in the background predictions are described in section 5.

The signal acceptance is obtained from MC simulations of the various signals processed through the full detector simulation (section 2). Systematic uncertainties in the final results are dominated by uncertainties in the differences between the simulation and data.
evaluated in control samples. The relevant differences are discussed below. A summary of
the systematic uncertainties is given in table 4.

The trigger acceptance is dominated by the muon triggers for all the models except
for the charge-suppressed scenarios. The uncertainty in the muon trigger acceptance arises
from several effects. A difference of up to 5% between data and MC simulation events
has been observed [58]. For slow moving particles, the effect of the timing synchronization
of the muon system is tested by shifting the arrival times in simulation to match the
synchronization offset and width observed in data, resulting in an acceptance change of 2%
(4%) for $\sqrt{s} = 7$ (8) TeV. For the $|Q| < 1e$ samples, an additional uncertainty arises from
the possibility of losing hits because their ionization in the muon system is closer to the
hit threshold. The uncertainty in the gains in the muon system is evaluated by shifting the
gain by 25%, yielding an acceptance change of 15% (3%) for $|Q| = e/3(2e/3)$ samples. The
uncertainty in the $E_T^{\text{miss}}$ trigger acceptance is found by varying, at HLT level, the energy of
simulated jets by the scale uncertainties. The $E_T^{\text{miss}}$ uncertainty for $\sqrt{s} = 7$ TeV samples is
estimated to be less than 2% for all scenarios except for the charge-suppressed ones, where
it is estimated to be <5%. For $\sqrt{s} = 8$ TeV samples it is less than 1% for all samples.

The energy loss in the silicon tracker is important for all the analyses except for the
muon-only one. Low-momentum protons are used to quantify the agreement between the
observed and simulated distributions for $I_h$ and $I_{as}$. The $dE/dx$ distributions of signal
samples are varied in the simulation by the observed differences, in order to determine
the systematic uncertainty. Because the fractionally charged analysis is also sensitive to
changes to the number of hits on the track, track reconstruction is also performed after
shifting $dE/dx$. The uncertainty in the signal acceptance varies by less than 24% for the
$|Q| = 1e$ samples, being less than 10% for all masses above 200 GeV/$c^2$. For the $|Q| < 1e$
samples, the effect of the $dE/dx$ shift and the track reconstruction combined is 25% (<10%)
for $|Q| = e/3(2e/3)$. The $|Q| > 1e$ samples have sufficient separation of the signal from the
final $I_{as}$ selection that the effect of the $dE/dx$ shift is negligible.

The Z boson decays to muons are used to test the MC simulation of the $1/\beta$ measure-
ment. At $\sqrt{s} = 7$ TeV, the $1/\beta$ measurement was observed to have a disagreement of 0.02
in the CSC system and 0.003 in the DT system. At $\sqrt{s} = 8$ TeV a disagreement of 0.005
is observed for both systems. The uncertainty in the signal acceptance is estimated to be
between 0 and 15% by shifting 1/$\beta$ by these amounts. The uncertainty is generally less
than 7% except for the high-charge/low-mass samples in the multiply charged analysis.

The uncertainties in the efficiencies for muon reconstruction [58] and track reconstruc-
tion [61] are less than 2% each. The track momentum uncertainty for the muon-only
analysis is determined by shifting 1/$p_T$ of muon system tracks by 10%. For all other anal-
yses, the momentum from the inner tracker track is varied as in ref. [24]. The uncertainty
is estimated to be <5% for all but the $|Q| < 1e$ samples, low-mass $|Q| > 1e$ samples, and
the muon-only scenarios, where the uncertainty is less than 10%.

The uncertainty in the number of pileup events is evaluated by varying by 5-6% the
minimum bias cross section used to calculate the weights applied to signal events in order
to reproduce the pileup observed in data. This results in uncertainties due to pileup of less
than 4%.
The uncertainty in the amount of material in the detector simulation results in an uncertainty in the signal trigger and reconstruction acceptance, particularly for the $|Q| > 1e$ samples. This is evaluated by increasing the amount of material in the hadronic calorimeter by a conservative 5\% [62]. Since it was not practical to evaluate the effect in detail for each value of $Q$ considered, the largest change in signal acceptance observed (~20\%) was assigned to all $|Q| > 1e$ scenarios. The change in signal acceptance is $\leq 1\%$ for all $|Q| \leq 1e$ scenarios.

The total systematic uncertainty in the signal acceptance for the tracker-only analysis is less than 32\% and is less than 11\% for all of the gluino and scalar top cases. For the tracker+TOF analysis it is less than 15\% for all cases except for $|Q| = 2e/3$, where the uncertainty ranges from 15\% to 31\%, being larger at low masses. The muon-only analysis has an uncertainty in the signal acceptance in the range of 7–13\%. The multiply charged analysis has an uncertainty in the signal acceptance in the range of 21–29\% for $|Q| > 1e$ samples and 7–13\% for $|Q| = 1e$ samples with both being larger at low masses. The fractionally charged analysis has an uncertainty in the signal acceptance of 31\% and 12\% for $|Q| = e/3$ and $2e/3$ samples, respectively.

The statistical uncertainty in the signal acceptance is small compared to the total systematic uncertainty for all the cases except for the low-mass highly charged scenarios, where the low acceptance leads to a statistical uncertainty that is comparable with the systematic uncertainties. For example, in the $|Q| = 6e$, $M = 100$ GeV/c$^2$ signal, the statistical uncertainty is as high as 30\%. In all cases the statistical uncertainty is taken into account when setting limits on signal cross sections.

7 Results

No significant excess of events is observed over the predicted backgrounds. The largest excess for any of the selections shown in table 3 has a significance of 1.3 standard deviations. Cross section limits are placed at 95\% confidence level (CL) for both $\sqrt{s} = 7$ and 8 TeV using

Table 4. Systematic uncertainties for the various HSCP searches.
the CL$_s$ approach \cite{63, 64} where $p$-values are computed with a hybrid bayesian-frequentist technique \cite{65} that uses a lognormal model \cite{54, 55} for the nuisance parameters. The latter are the integrated luminosity, the signal acceptance, and the expected background in the signal region. The uncertainty in the theoretical cross section is not considered as a nuisance parameter. For the combined dataset, the limits are instead placed on the signal strength ($\mu = \sigma/\sigma_{th}$). Limits on the signal strength using only the 8 TeV dataset for the muon-only analysis are also presented. The observed limits are shown in figures 8–10 for all the analyses along with the theoretical predictions. For the gluino and scalar top pair production, the theoretical cross sections are computed at NLO+NLL \cite{45–48} using PROSPINO \cite{66} with CTEQ6.6M PDFs \cite{67}. The uncertainty bands on the theoretical cross sections include the PDF uncertainty, as well as the $\alpha_s$ and scale uncertainties. Mass limits are obtained from the intersection of the observed limit and the central value of the theoretical cross section. For the combined result, the masses for which the signal strength is less than one are excluded.

From the final results, 95% CL limits on the production cross section are shown in tables 5, 6, 7, and 8 for gluino, scalar top, stau, and for Drell-Yan like production of fractionally, singly, or multiply charged particles, respectively. The limits are determined from the numbers of events passing all final criteria (including the mass criteria for the tracker-only and tracker+TOF analyses). Figure 8 shows the limits as a function of mass for the tracker-only and tracker+TOF analyses. The tracker-only analysis excludes gluino masses below 1322 and 1233 GeV/c$^2$ for $f = 0.1$ in the cloud interaction model and charge-suppressed model, respectively. Stop masses below 935 (818) GeV/c$^2$ are excluded for the cloud (charge-suppressed) models. In addition, the tracker+TOF analysis excludes $\tilde{\tau}_1$ masses below 500 (339) GeV/c$^2$ for the direct+indirect (direct only) production. Drell-Yan signals with $|Q| = 2e/3$ and $|Q| = 1e$ are excluded below 220 and 574 GeV/c$^2$, respectively.

The limits from the muon-only analysis for the scalar top and the gluino with various hadronization fractions $f$ are shown in figure 9. The muon-only analysis excludes gluino masses below 1250(1276) GeV/c$^2$ for $f = 1.0(0.5)$.

Figure 10 shows the limits applied to the Drell-Yan production model for both the fractionally charged and multiply charged analyses. The fractionally charged analysis excludes masses below 200 and 480 GeV/c$^2$ for $|Q| = e/3$ and $2e/3$, respectively. The multiply charged analysis excludes masses below 685, 752, 793, 796, 781, 757, and 715 GeV/c$^2$ for $|Q| = 2e, 3e, 4e, 5e, 6e, 7e,$ and $8e$, respectively. The multiply charged analysis is not optimized for singly charged particles but can set a limit and is able to exclude masses below 517 GeV/c$^2$. As expected, this limit is not as stringent as the one set by the tracker+TOF analysis but does allow results to be interpolated to non-integer charge values (such as $|Q| = 3e/2, 4e/3$) using results from the same analysis.

The mass limits for various signals and electric charges are shown in figure 11 and are compared with previously published results.

The limits obtained for the reanalyzed $\sqrt{s} = 7$ TeV dataset are similar to the previously published CMS results except for the stau scenarios, where the new cross section limits are slightly worse than the previously published ones. This result is a consequence of having a common selection for all mass points and models in contrast to what was done in ref. \cite{24},
Figure 8. Upper cross section limits at 95% CL on various signal models for the tracker-only analysis (left column) and tracker+TOF analysis (right column). The top row is for the data at $\sqrt{s} = 7$ TeV, the middle row is for the data at $\sqrt{s} = 8$ TeV, the bottom row shows the ratio of the limit to the theoretical value for the combined dataset. In the legend, 'CS' stands for the charge-suppressed interaction model.
Figure 9. Upper cross section limits at 95% CL on various signal models for the muon-only analysis for the data at $\sqrt{s} = 8$ TeV (left). Limits on the signal strength ($\mu = \sigma/\sigma_{\text{th}}$) for the same data (right).

where the selection was optimized separately for each mass point and model. However, the use of a higher NLO cross section for the indirect production of staus than in ref. [24] results in more stringent limits on the stau mass.

The mass limit for |Q| < 1e samples are significantly improved with respect to ref. [23], thanks to a different analysis approach and to the use of the $I'_a$ likelihood discriminator that maximally exploits all the dE/dx information associated with a track.

8 Summary

A search for heavy stable charged particles has been presented, based on several different signatures, using data recorded at collision energies of 7 and 8 TeV. Five complementary analyses have been performed: a search with only the inner tracker, a search with both the inner tracker and the muon system, a search with only the muon system, a search for low ionizing tracks, and a search for tracks with very large ionization energy loss. No significant excess is observed in any of the analyses. Limits on cross sections are presented...

Table 8. Expected and observed cross section limits and the signal acceptance for the Drell-Yan like production of fractionally, singly, and multiply charged particles at √s = 7 and 8 TeV, as well as the ratio of the cross section limit to the theoretical value for the combined dataset. The minimum reconstructed mass required (M req.) for each sample in the tracker+TOF analysis is also given.
Figure 11. Lower mass limits at 95% CL for various models compared with previously published results [19–26]. The model type is given on the x-axis (left). Mass limits are shown for Drell-Yan like production of fractionally, singly, and multiply charged particles (right). These particles were assumed to be neutral under SU(3)$_{C}$ and SU(2)$_{L}$.

for models with the production of gluinos, scalar tops, and staus, and for Drell-Yan like production of fractionally, singly, and multiply charged particles. The models for $R$-hadron-like HSCPs include a varying fraction of $\tilde{g}$—gluon production and two different interaction schemes leading to a variety of non-standard experimental signatures. Lower mass limits for these models are given. Gluino masses below 1322 and 1233 GeV$/c^2$ are excluded for $f = 0.1$ in the cloud interaction model and the charge-suppressed model, respectively. For $f = 0.5$ (1.0), gluino masses below 1276 (1250) GeV$/c^2$ are excluded. For stop production, masses below 935 (818) GeV$/c^2$ are excluded for the cloud (charge-suppressed) models. In addition, these analyses exclude $\tilde{\tau}_1$ masses below 500 (339) GeV$/c^2$ for the direct+indirect (direct only) production. Drell-Yan like signals with $|Q| = e/3, 2e/3, 1e, 2e, 3e, 4e, 5e, 6e, 7e, 8e$ are excluded with masses below 200, 480, 574, 685, 752, 793, 796, 781, 757, and 715 GeV$/c^2$, respectively. These limits are the most stringent to date.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centres and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MEYS (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES (Croatia); RPF (Cyprus); MoER, SF0690030s09 and ERDF (Estonia);
Individuals have received support from the Marie-Curie programme and the European Research Council and EPLANET (European Union); the Leventis Foundation; the A. P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l’Industrie et dans l’Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of Czech Republic; the Council of Science and Industrial Research, India; the Compagnia di San Paolo (Torino); the HOMING PLUS programme of Foundation for Polish Science, co-financed by EU, Regional Development Fund; and the Thalis and Aristeia programmes cofinanced by EU-ESF and the Greek NSRF.

A. Avetisyan, T. Bose, C. Fantasia, A. Heister, P. Lawson, D. Lazić, J. Rohlf, D. Sperka, J. St. John, L. Sulak

Brown University, Providence, USA

University of California, Davis, Davis, USA

University of California, Los Angeles, USA

University of California, Riverside, Riverside, USA

University of California, San Diego, La Jolla, USA

University of California, Santa Barbara, Santa Barbara, USA

California Institute of Technology, Pasadena, USA

Carnegie Mellon University, Pittsburgh, USA
V. Azzolini, A. Calamba, R. Carroll, T. Ferguson, Y. Iiyama, D.W. Jang, Y.F. Liu, M. Paulini, J. Russ, H. Vogel, I. Vorobiev
University of Colorado at Boulder, Boulder, USA

Cornell University, Ithaca, USA

Fairfield University, Fairfield, USA
D. Winn

Fermi National Accelerator Laboratory, Batavia, USA

University of Florida, Gainesville, USA

Florida International University, Miami, USA

Florida State University, Tallahassee, USA

Florida Institute of Technology, Melbourne, USA
M.M. Baarmand, B. Dorney, M. Hohlmann, H. Kalakhety, F. Yumiceva

University of Illinois at Chicago (UIC), Chicago, USA
Northeastern University, Boston, USA

Northwestern University, Evanston, USA

University of Notre Dame, Notre Dame, USA

The Ohio State University, Columbus, USA
L. Antonelli, B. Bylsma, L.S. Durkin, C. Hill, R. Hughes, K. Kotov, T.Y. Ling, D. Puigh, M. Rodenburg, G. Smith, C. Vuosalo, G. Williams, B.L. Winer, H. Wolfe

Princeton University, Princeton, USA

University of Puerto Rico, Mayaguez, USA
E. Brownson, A. Lopez, H. Mendez, J.E. Ramirez Vargas

Purdue University, West Lafayette, USA

Purdue University Calumet, Hammond, USA
S. Guragain, N. Parashar

Rice University, Houston, USA
A. Adair, B. Akgun, K.M. Ecklund, F.J.M. Geurts, W. Li, B.P. Padley, R. Redjimi, J. Roberts, J. Zabel

University of Rochester, Rochester, USA
B. Betchart, A. Bodek, R. Covarelli, P. de Barbaro, R. Demina, Y. Eshaq, T. Ferbel, A. Garcia-Bellido, P. Goldenzweig, J. Han, A. Harel, D.C. Miner, G. Petrillo, D. Vishnevskiy, M. Zielinski

The Rockefeller University, New York, USA
A. Bhatti, R. Ciesielski, L. Demortier, K. Goulianos, G. Lungu, S. Malik, C. Mesropian

Rutgers, The State University of New Jersey, Piscataway, USA
S. Arora, A. Barker, J.P. Chou, C. Contreras-Campana, E. Contreras-Campana, D. Duggan, D. Ferencek, Y. Gershtein, R. Gray, E. Halkiadakis, D. Hidas, A. Lath, S. Panwalkar,

University of Tennessee, Knoxville, USA
G. Cerizza, M. Hollingsworth, S. Spanier, Z.C. Yang, A. York

Texas A&M University, College Station, USA

Texas Tech University, Lubbock, USA
N. Akchurin, J. Damgov, C. Dragoiu, P.R. Dudero, C. Jeong, K. Kovitanggoon, S.W. Lee, T. Libeiro, I. Volobouev

Vanderbilt University, Nashville, USA

University of Virginia, Charlottesville, USA

Wayne State University, Detroit, USA
S. Gollapinni, R. Harr, P.E. Karchin, C. Kottachchi Kankanamge Don, P. Lamichhane, A. Sakharov

University of Wisconsin, Madison, USA

\textsuperscript{†}: Deceased
1: Also at Vienna University of Technology, Vienna, Austria
2: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
3: Also at Institut Pluridisciplinaire Hubert Curien, Université de Strasbourg, Université de Haute Alsace Mulhouse, CNRS/IN2P3, Strasbourg, France
4: Also at National Institute of Chemical Physics and Biophysics, Tallinn, Estonia
5: Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia
6: Also at Universidade Estadual de Campinas, Campinas, Brazil
7: Also at California Institute of Technology, Pasadena, USA
8: Also at Laboratoire Leprince-Ringuet, Ecole Polytechnique, IN2P3-CNRS, Palaiseau, France
9: Also at Suez Canal University, Suez, Egypt
10: Also at Cairo University, Cairo, Egypt
11: Also at Fayoum University, El-Fayoum, Egypt
12: Also at Helwan University, Cairo, Egypt
13: Also at British University in Egypt, Cairo, Egypt
14: Now at Ain Shams University, Cairo, Egypt
15: Also at National Centre for Nuclear Research, Swierk, Poland
16: Also at Université de Haute Alsace, Mulhouse, France
17: Also at Joint Institute for Nuclear Research, Dubna, Russia
18: Also at Brandenburg University of Technology, Cottbus, Germany
19: Also at The University of Kansas, Lawrence, USA
20: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
21: Also at Eötvös Loránd University, Budapest, Hungary
22: Also at Tata Institute of Fundamental Research - HECR, Mumbai, India
23: Now at King Abdulaziz University, Jeddah, Saudi Arabia
24: Also at University of Visva-Bharati, Santiniketan, India
25: Also at University of Ruhuna, Matara, Sri Lanka
26: Also at Sharif University of Technology, Tehran, Iran
27: Also at Isfahan University of Technology, Isfahan, Iran
28: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Tehran, Iran
29: Also at Laboratori Nazionali di Legnaro dell’ INFN, Legnaro, Italy
30: Also at Università degli Studi di Siena, Siena, Italy
31: Also at Universidad Michoacana de San Nicolas de Hidalgo, Morelia, Mexico
32: Also at Faculty of Physics, University of Belgrade, Belgrade, Serbia
33: Also at Facoltà Ingegneria, Università di Roma, Roma, Italy
34: Also at Scuola Normale e Sezione dell’INFN, Pisa, Italy
35: Also at INFN Sezione di Roma, Roma, Italy
36: Also at University of Athens, Athens, Greece
37: Also at Rutherford Appleton Laboratory, Didcot, United Kingdom
38: Also at Paul Scherrer Institut, Villigen, Switzerland
39: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia
40: Also at Albert Einstein Center for Fundamental Physics, Bern, Switzerland
41: Also at Gaziosmanpasa University, Tokat, Turkey
42: Also at Adiyaman University, Adiyaman, Turkey
43: Also at Cag University, Mersin, Turkey
44: Also at Mersin University, Mersin, Turkey
45: Also at Izmir Institute of Technology, Izmir, Turkey
46: Also at Ozyegin University, Istanbul, Turkey
47: Also at Kafkas University, Kars, Turkey
48: Also at Suleyman Demirel University, Isparta, Turkey
49: Also at Ege University, Izmır, Turkey
50: Also at Mimar Sinan University, Istanbul, Istanbul, Turkey
51: Also at Kahramanmaraş Sütçü İmam University, Kahramanmaraş, Turkey
52: Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom
53: Also at INFN Sezione di Perugia; Università di Perugia, Perugia, Italy
54: Also at Utah Valley University, Orem, USA
55: Now at University of Edinburgh, Scotland, Edinburgh, United Kingdom
56: Also at Institute for Nuclear Research, Moscow, Russia
57: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
58: Also at Argonne National Laboratory, Argonne, USA
59: Also at Erzincan University, Erzincan, Turkey
60: Also at Yildiz Technical University, Istanbul, Turkey
61: Also at Kyungpook National University, Daegu, Korea
